Complexity

- Why worry about complexity of algorithms?
- because a problem may be solvable in principle but may take too long to solve in practice

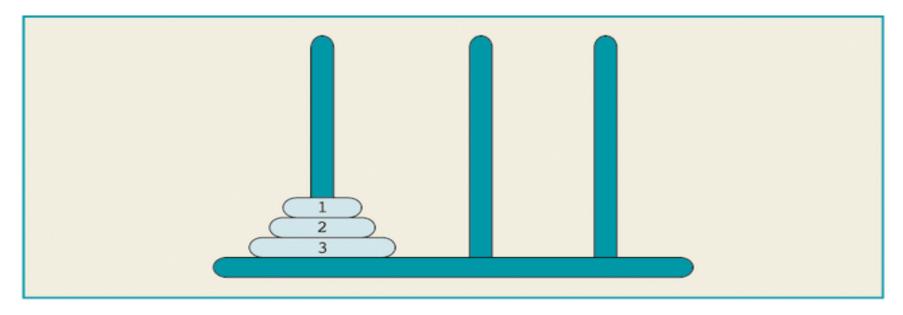

Figure 11-6 Tower of Hanoi problem with three disks

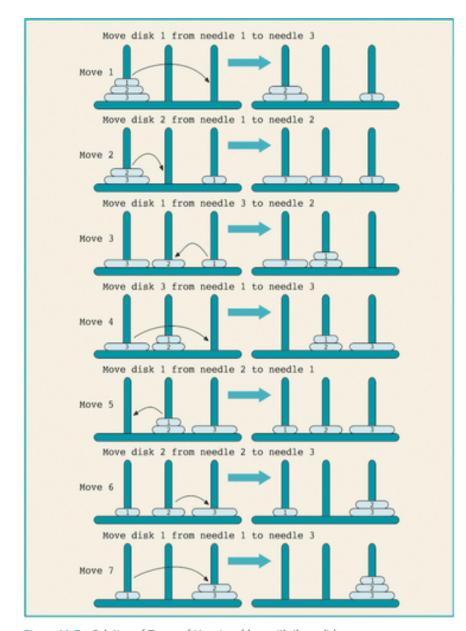

Figure 11-7 Solution of Tower of Hanoi problem with three disks

CSCI 561, Lecture 4

• 3-disk problem: $2^3 - 1 = 7$ moves

• 64-disk problem: 2⁶⁴ – 1.

•
$$2^{10} = 1024 \approx 1000 = 10^3$$

$$\bullet$$
 2⁶⁴ = 2⁴ * 2⁶⁰ \approx 2⁴ * 10¹⁸ = 1.6 * 10¹⁹

• One year \approx 3.2 * 10⁷ seconds

The wizard's speed = one disk / second

$$1.6 * 10^{19} = 5 * 3.2 * 10^{18} =$$
 $5 * (3.2 * 10^{7}) * 10^{11} =$
 $(3.2 * 10^{7}) * (5 * 10^{11})$

- The time required to move all 64 disks from needle
 1 to needle 3 is roughly 5 * 10¹¹ years.
- It is estimated that our universe is about 15 billion
 = 1.5 * 10¹⁰ years old.

$$5 * 10^{11} = 50 * 10^{10} \approx 33 * (1.5 * 10^{10})$$

- Assume: a computer with 1 billion = 10° moves/second.
 - Moves/year= $(3.2 *10^7) * 10^9 = 3.2 * 10^{16}$
- To solve the problem for 64 disks:
 - $2^{64} \approx 1.6 * 10^{19} = 1.6 * 10^{16} * 10^{3} =$ $(3.2 * 10^{16}) * 500$
 - 500 years for the computer to generate 264 moves at the rate of 1 billion moves per second.

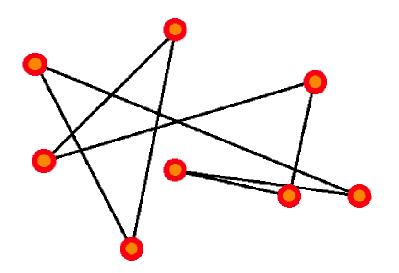

Complexity

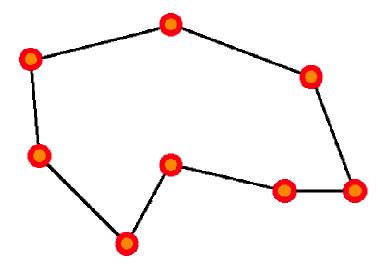

- Why worry about complexity of algorithms?
- because a problem may be solvable in principle but may take too long to solve in practice
- How can we evaluate the complexity of algorithms?
- ➤ through asymptotic analysis, i.e., estimate time (or number of operations) necessary to solve an instance of size n of a problem when n tends towards infinity
- ➤ See AIMA, Appendix A.

Complexity example: Traveling Salesman Problem

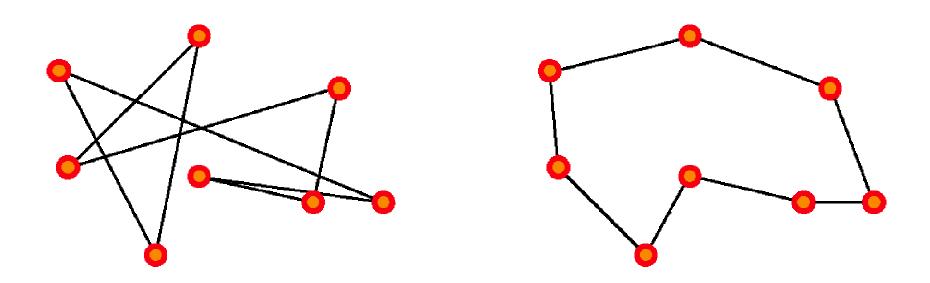

- There are n cities, with a road of length L_{ij} joining city i to city j.
- The salesman wishes to find a way to visit all cities that is optimal in two ways:

each city is visited only once, and the total route is as short as possible.

Complexity example: Traveling Salesman Problem

This is a *hard* problem: the only known algorithms (so far) to solve it have exponential complexity, that is, the number of operations required to solve it grows as *exp(n)* for *n* cities.

Why is exponential complexity "hard"?

It means that the number of operations necessary to compute the exact solution of the problem grows exponentially with the size of the problem (here, the number of cities).

```
• exp(1) = 2.72
```

- $exp(10) = 2.20 \ 10^4$ (daily salesman trip)
- $exp(100) = 2.69 \ 10^{43}$ (monthly salesman planning)
- $exp(500) = 1.40 \ 10^{217}$ (music band worldwide tour)
- $\exp(250,000) = 10^{108,573}$ (fedex, postal services)
- Fastest computer = 10^{12} operations/second

So...

In general, exponential-complexity problems *cannot be* solved for any but the smallest instances!

Complexity

 Polynomial-time (P) problems: we can find algorithms that will solve them in a time (=number of operations) that grows polynomially with the size of the input.

For example: sort n numbers into increasing order: poor algorithms have n^2 complexity, better ones have $n \log(n)$ complexity.

Complexity

- Since we did not state what the order of the polynomial is, it could be very large! Are there algorithms that require more than polynomial time?
- Yes (until proof of the contrary); for some algorithms, we do not know of any polynomial-time algorithm to solve them. These belong to the class of nondeterministic-polynomial-time (NP) algorithms (which includes P problems as well as harder ones).
- for example: traveling salesman problem.
- In particular, exponential-time algorithms are believed to be NP.

Note on NP-hard problems

The formal definition of NP problems is:

A problem is nondeterministic polynomial if there exists some algorithm that can guess a solution and then verify whether or not the guess is correct in polynomial time.

(one can also state this as these problems being solvable in polynomial time on a nondeterministic Turing machine.)

In practice, until proof of the contrary, this means that known algorithms that run on known computer architectures will take more than polynomial time to solve NP problems.

CSCI 561, Lecture 4

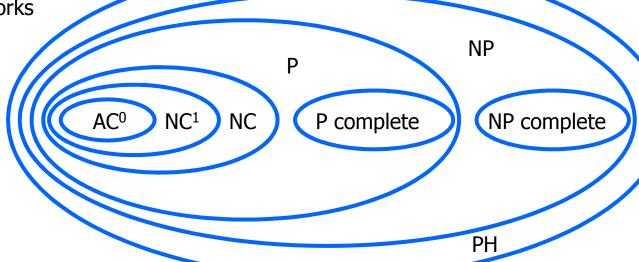

Polynomial-time hierarchy

From Handbook of Brain

Theory & Neural Networks

(Arbib, ed.;

MIT Press 1995).

AC⁰: can be solved using gates of constant depth

NC1: can be solved in logarithmic depth using 2-input gates

NC: can be solved by small, fast parallel computer

P: can be solved in polynomial time

P-complete: hardest problems in P; if one of them can be proven to be

NC, then P = NC

NP: nondeterministic-polynomial algorithms

NP-complete: hardest NP problems; if one of them can be proven to be

P, then NP = P

PH: polynomial-time hierarchy

Remember: Implementation of search algorithms

```
Function General-Search(problem, Queuing-Fn) returns a solution, or failure
  nodes ← make-queue(make-node(initial-state[problem]))
loop do
  if nodes is empty then return failure
  node ← Remove-Front(nodes)
  if Goal-Test[problem] applied to State(node) succeeds then return node
  nodes ← Queuing-Fn(nodes, Expand(node, Operators[problem]))
end
```

Queuing-Fn(*queue, elements***)** is a queuing function that inserts a set of elements into the queue and <u>determines the order of node expansion</u>. Varieties of the queuing function produce varieties of the search algorithm.

Evaluation of search strategies

A search strategy is defined by picking the order of node expansion.

- Search algorithms are commonly evaluated according to the following four criteria:
 - **Completeness:** does it always find a solution if one exists?
 - **Time complexity:** how long does it take as function of num. of nodes?
 - **Space complexity:** how much memory does it require?
 - Optimality: does it guarantee the least-cost solution?
- Time and space complexity are measured in terms of:
 - $b \max$ branching factor of the search tree
 - *d* depth of the least-cost solution
 - $m \max$ depth of the search tree (may be infinity)

Note: Approximations

- In our complexity analysis, we do not take the built-in <u>loop-detection</u> into account.
- The results only 'formally' apply to the variants of our algorithms WITHOUT loop-checks.
- Studying the effect of the loop-checking on the complexity is hard:
 - overhead of the checking MAY or MAY NOT be compensated by the reduction of the size of the tree.
- Also: our analysis DOES NOT take the length (space) of representing paths into account !!

Uninformed search strategies

Use only information available in the problem formulation

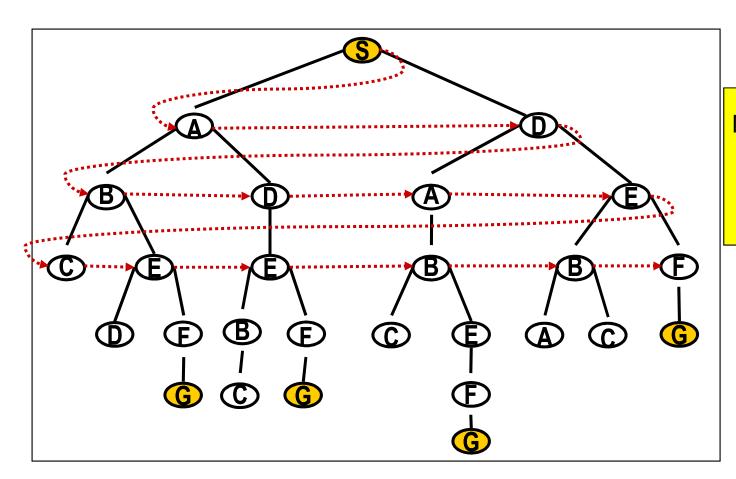

- Breadth-first
- Uniform-cost
- Depth-first
- Depth-limited
- Iterative deepening

Expand shallowest unexpanded node

Implementation:

 $\mathrm{QUEUEINGFN} = \mathsf{put}$ successors at end of queue

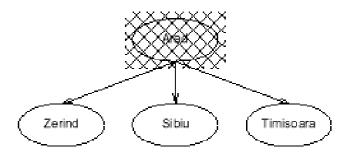

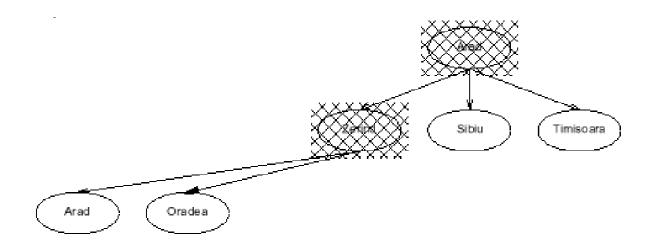

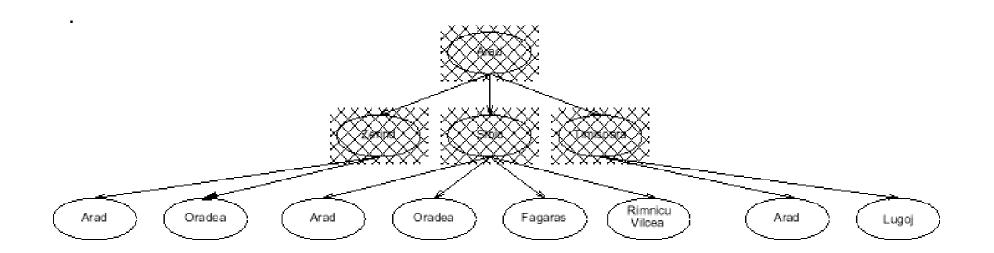

Move downwards, level by level, until goal is reached.

Example: Traveling from Arad To Bucharest

Properties of breadth-first search

Completeness: Yes, if b is finite

• Time complexity: $1+b+b^2+...+b^d = O(b^d)$, i.e., exponential in d

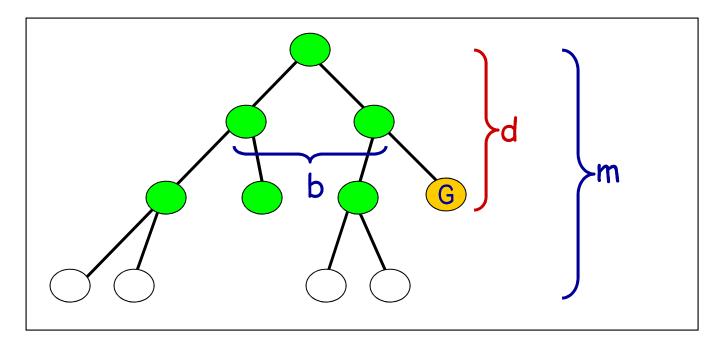

• Space complexity: $O(b^d)$ (see following slides)

Optimality: Yes, assuming cost = 1 per step

- Search algorithms are commonly evaluated according to the following four criteria:
 - Completeness: does it always find a solution if one exists?
 - Time complexity: how long does it take as function of num. of nodes?
 - Space complexity: how much memory does it require?
 - Optimality: does it guarantee the least-cost solution?
- Time and space complexity are measured in terms of:
 - *b* − max branching factor of the search tree
 - *d* depth of the least-cost solution
 - *m* max depth of the search tree (may be infinity)

Time complexity of breadth-first search

 If a goal node is found on depth d of the tree, all nodes up till that depth are created.

• <u>Thus</u>: O(b^d)

Space complexity of breadth-first

 Largest number of nodes in QUEUE is reached on the level d of the goal node.

- QUEUE contains all and G nodes. (Thus: 4).
- In General: b^d

Expand least-cost unexpanded node

Implementation:

QUEUEINGFN = insert in order of increasing path cost

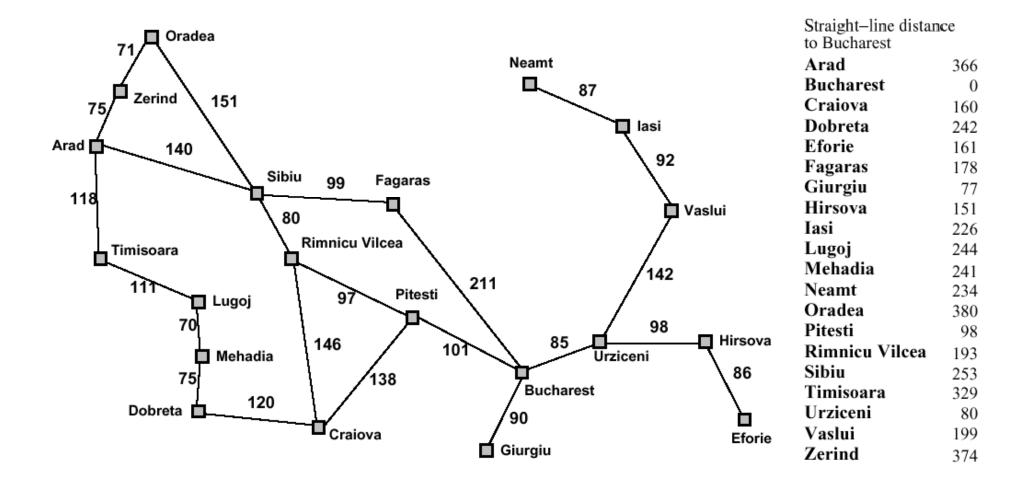

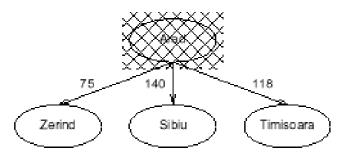

So, the queueing function keeps the node list sorted by increasing path cost, and we expand the first unexpanded node (hence with smallest path cost)

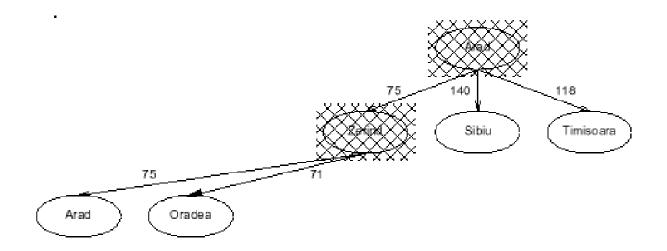

A refinement of the breadth-first strategy:

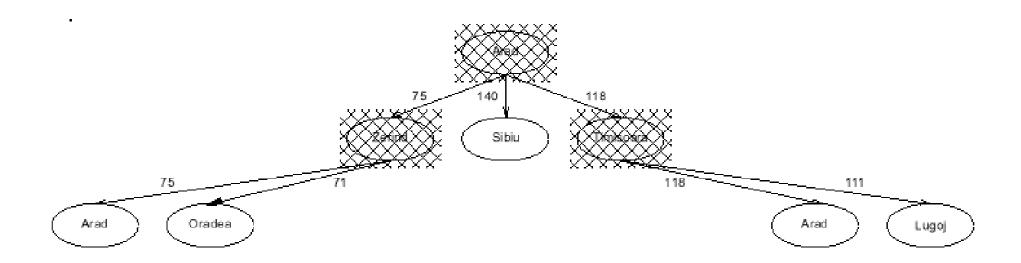

Breadth-first = uniform-cost with path cost = node depth

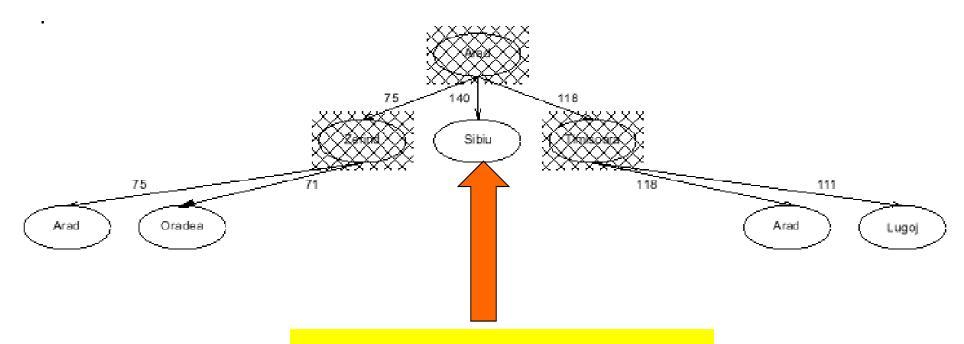

Romania with step costs in km

Next node to be expanded because of least path cost

Properties of uniform-cost search

• Completeness: Yes, if step cost $\geq \varepsilon > 0$

• Time complexity: # nodes with $g \le cost$ of optimal solution, $\le O(b^d)$

• Space complexity: # nodes with $g \le cost$ of optimal solution, $\le O(b^d)$

• Optimality: Can be optimal if you do not terminate the search after reaching a goal state AND if step cost $\geq \varepsilon > 0$

g(n) is the path cost to node n Remember:

b = branching factor

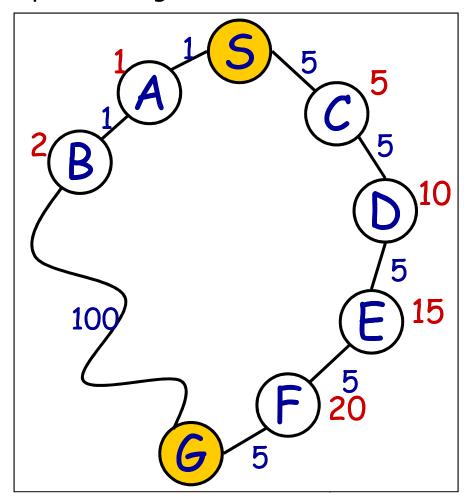

d = depth of least-cost solution

Implementation of uniform-cost search

- Initialize Queue with root node (built from start state)
- Repeat until (Queue empty) or (first node has Goal state):
 - Remove first node from front of Queue
 - Expand node (find its children)
 - Reject those children that have already been considered, to avoid loops
 - Add remaining children to Queue, in a way that keeps entire queue sorted by increasing path cost
- If Goal was reached, return success, otherwise failure

Caution!

 Uniform-cost search <u>not</u> optimal if it is terminated when *any* node in the queue has goal state.

Uniform cost returns
 the path with cost
 102 (if first
 encounter of any
 goal node is
 considered a
 solution), while there
 is a path with cost
 25! So, do not
 terminate till G itself
 needs to be
 expanded

Note: Loop Detection

- In class, we saw that the search may fail or be sub-optimal if:
 - no loop detection: then algorithm runs into infinite cycles (A -> B -> A -> B -> ...)
 - not queuing-up a node that has a state which we have already visited: may yield suboptimal solution
 - simply avoiding to go back to our parent: looks promising, but we have not proven that it works

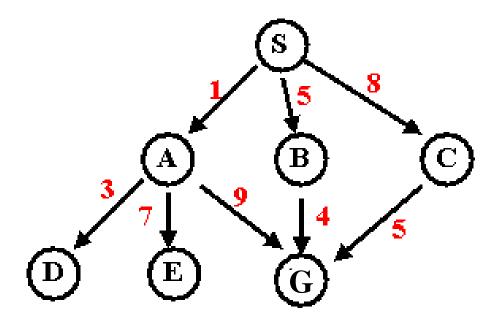

Solution? do not enqueue a node if its state matches the state of any of its parents (assuming path costs>0).

Indeed, if path costs > 0, it will always cost us more to consider a node with that state again than it had already cost us the first time.

Example

From: http://www.csee.umbc.edu/471/current/notes/uninformed-search/

Example Illustrating Uninformed Search Strategies

Breadth-First Search Solution

From: http://www.csee.umbc.edu/471/current/notes/uninformed-search/

Breadth-First Search

return GENERAL-SEARCH(problem, ENQUEUE-AT-END) exp. node nodes list

```
(S)
S (ABC)
A (BCDEG)
B (CDEGG')
C (DEGG'G")
D (EGG'G")
E (GG'G")
G (G'G")
```

Solution path found is SAG <-- this Galso has cost 10

Number of nodes expanded (including goal node) = 7

Uniform-Cost Search Solution

From: http://www.csee.umbc.edu/471/current/notes/uninformed-search/

Uniform-Cost Search

GENERAL-SEARCH(problem, ENQUEUE-BY-PATH-COST)

exp. node nodes list

```
(S)
S (A(1) B(5) C(8) }
A (D(4) B(5) C(8) E(8) G(10) } (NB, we don't return G)
D (B(5) C(8) E(8) G(10) }
B (C(8) E(8) G(9) G(10) }
C (E(8) G(9) G(10) G(13) }
E (G(9) G(10) G(13) }
G ()
```

Solution path found is SBG <-- this Ghas cost 9, not 10

Number of nodes expanded (including goal node) = 7

Note: Queuing in Uniform-Cost Search

In the previous example, it is wasteful (but not incorrect) to queue-up three nodes with G state, if our goal if to find the least-cost solution:

Although they represent different paths, we know for sure that the one with smallest path cost (9 in the example) will yield a solution with smaller total path cost than the others.

So we can refine the queueing function by:

- queue-up node if
 - 1) its state does not match the state of any parent

and

2) path cost smaller than path cost of any unexpanded node with same state in the queue (and in this case, replace old node with same state by our new node)
